(Received 20 November 2016; accepted 16 February 2017; published online 6 March 2017)

Large area epitaxy of two-dimensional (2D) layered materials with high material quality is a crucial step in realizing novel device applications based on 2D materials. In this work, we report high-quality, crystalline, large-area gallium selenide (GaSe) films grown on bulk substrates such as c-plane sapphire and gallium nitride (GaN) using a valved cracker source for Se. (002)-Oriented GaSe with random in-plane orientation of domains was grown on sapphire and GaN substrates at a substrate temperature of 350–450 °C with complete surface coverage. Higher growth temperature (575 °C) resulted in the formation of single-crystalline ε-GaSe triangular domains with six-fold symmetry confirmed by in-situ reflection high electron energy diffraction and off-axis x-ray diffraction. A two-step growth method involving high temperature nucleation of single crystalline domains and low temperature growth to enhance coalescence was adopted to obtain continuous (002)-oriented GaSe with an epitaxial relationship with the substrate. While six-fold symmetry was maintained in the two step growth, β-GaSe phase was observed in addition to the dominant ε-GaSe in cross-sectional scanning transmission electron microscopy images. This work demonstrates the potential of growing high quality 2D-layered materials using molecular beam epitaxy and can be extended to the growth of other transition metal chalcogenides. Published by AIP Publishing. [http://dx.doi.org/10.1063/1.4977697]

I. INTRODUCTION

Two-dimensional (2D) metal chalcogenides are of great scientific interest for electronic as well as optical devices due to their unique structural, electrical, and mechanical properties, such as wide range of bandgaps,1,2 valley-polarized carriers,3,4 strong spin–orbit coupling,5 and superconductivity.6 Recently, artificial stacking of these layered materials is being heavily explored to create heterostructures for novel applications. Most of these studies have been carried out by transferring layered flakes or films from minerals7–9 or synthesized materials obtained using chemical vapor transport (CVT)10,11 or chemical vapor deposition (CVD) methods.12,13 In contrast to such stacking methods, epitaxial techniques such as metal organic chemical vapor deposition and molecular beam epitaxy (MBE) provide a more practical approach to achieving large area epitaxial materials with precise control of layer thickness and doping. In addition, the absence of out-of-plane dangling bonds in layered materials can enable van der Waals epitaxy (vdWE) on highly lattice-mismatched substrate without lattice matching constraints.14,15 For instance, growth of gallium selenide (GaSe) on mica substrates with a significant lattice mismatch of 35% has been reported.14 Van der Waals epitaxy was first introduced by Koma and co-workers15 and has been proven to be a powerful route to realize heteroepitaxy of 2D materials. More recently, renewed interest in 2D materials has led to the exploration of MBE growth of several materials, including GaSe,16–18 MoSe2,19–23 WSe2,24 and HfSe2.25 In this work, we report our work on growth of GaSe, which has a layered crystal structure consisting of repeating units of covalently bonded Se-Ga-Ga-Se held together by weak van der Waals force. Layered GaSe, however, occurs in several polytypes displaying different stacking sequences, leading to ε-, β-, γ-, and δ- phases of the material.26 Most common polytypes, ε (consists of two layers per unit cell and has the space group, D1h), and β (consists of two layers and has the space group, D4h), have a 2H stacking sequence.27 Bulk ε-GaSe is a 2 eV direct bandgap semiconductor and has been explored for applications in nonlinear optics, photovoltaics, and photodetectors.28,29

Single crystal MBE growth of GaSe on GaAs(111)B substrates has been reported by Ueno et al.30 It has also been shown that GaSe and Ga2Se3 can be grown on GaAs (001) substrates depending on the surface reconstruction.31 Vinh et al. demonstrated the growth of single crystal GaSe film on Si(111) substrate with 7 × 7 surface reconstruction.32 In addition, recent studies report that the growth of GaSe on sapphire substrates produces crystalline films with random in-plane orientation of the domains.16 However, there have not been reports on GaSe growth on wide bandgap semiconductors such as gallium nitride (GaN). Epitaxially grown high quality 2D materials on GaN can enable vertical 2D/3D heterostructures33,34 that can
enable vertical tunneling devices,\textsuperscript{33} heterojunction bipolar transistors (HBT), and hot electron transistors. We demonstrate the growth of highly crystalline centimeter-scale few layer GaSe films on bulk 3D materials such as sapphire and GaN. First, we have investigated the growth of continuous GaSe film on sapphire substrates at various growth conditions and utilized the optimized condition to grow GaSe on a GaN substrate. We report a two-step growth method to grow crystalline GaSe on GaN substrates by employing a high temperature nucleation step for growth of single crystal domains followed by the second step at lower growth temperature to achieve coalescence of the film.

II. EXPERIMENTAL METHODS

MBE growths were performed in a Veeco Gen930 system with a standard thermal effusion cell for gallium. While previous reports on GaSe growth use the standard Knudson-type effusion cell to evaporate selenium, in this work, we use a valved cracker source to supply Se. Se was evaporated using a valved cracker source with the cracker zone at 950°C in order to obtain Se\textsubscript{2} species of Se.\textsuperscript{35,36} Growth was monitored in-situ using reflection high-energy electron diffraction (RHEED). Prior to the growth, c-plane sapphire and Fe-doped insulating GaN(0001)/sapphire substrates were solvent cleaned, annealed at 400°C under ultra-high vacuum conditions (1 \times 10^{-7}Torr), and loaded into the growth chamber (base pressure 7 \times 10^{-10}Torr). Sapphire substrates were then annealed at 850°C in the growth chamber for 30 min before ramping down the substrate temperature for GaSe growth (400–500°C). The Gallium sub-oxides on GaN substrates were removed in-situ prior to the growth by using the following Ga polish technique. GaN substrates were exposed to a Ga flux of \approx 1 \times 10^{-8}Torr until the RHEED showed an amorphous pattern at 400°C. The substrate was then heated to 700°C for 30 min, followed by a ramp down to the growth temperature. Streaky RHEED patterns with Kikuchi line patterns were obtained prior to initiation of GaSe growths on sapphire and GaN substrates. The substrate temperature was measured using the thermocouple attached with the continuous azimuthal rotation (CAR) heater. The beam-equivalent pressure (BEP) of Se was fixed at 1 \times 10^{-6} and 1 \times 10^{-5}Torr during growth and was measured using a nude ion gauge with a tungsten filament. Samples were grown at different substrate temperatures (350–600°C) and Ga:Se flux ratios. The growth was initiated by opening the Se shutter for 2 min followed by opening of the Ga source at the growth temperature.

The crystalline quality of the GaSe films was evaluated through X-ray diffraction (XRD) (Bruker, D8 Discover) and Raman spectra (Renishaw) with a 1 mW laser at 514 nm. The surface morphology of the samples was examined by atomic force microscopy (AFM) (Veeco Instrument, DI 3000). The microstructure of GaSe was examined by cross-sectional scanning transmission electron microscopy (STEM). Due to the oxidation of GaSe in ambient conditions,\textsuperscript{37} AFM scans were performed immediately after the growth. XRD was measured after covering the GaSe surface with SPR955 photoresist. For the STEM measurements, the photoresist was removed using solvents and the surface was capped with Au metal immediately to prevent oxidation. Graphical illustrations of GaSe crystal structure was generated using VESTA software.\textsuperscript{38}

III. RESULTS AND DISCUSSION

Growth of GaSe was explored on c-plane sapphire substrates by varying the substrate temperature and the Ga:Se flux ratio. C-plane sapphire was chosen due to the hexagonal symmetry of the basal plane, which is similar to that of GaSe, and the high chemical and thermal stability of sapphire. The substrate temperature was varied from 350°C to 500°C, while changing the Ga:Se ratio from 1:50 to 1:200, and holding the Se flux at 1 \times 10^{-6}Torr. Growth was performed for one hour. The Se shutter was opened for two minutes and the streaky RHEED pattern of sapphire substrates (Fig. 1(a)) remained before the opening of the Ga shutter indicating that the sticking of Se adatoms is very poor in the absence of Ga flux. Upon opening the Ga shutter, the RHEED pattern corresponding to m- (10 0) and a- (11 2 0) planes of GaSe was observed, and the RHEED pattern did not change along the different azimuths (i.e., in-plane rotation of the substrate). The coexistence of the RHEED patterns corresponding to the m- and a-planes of GaSe was also reported earlier.\textsuperscript{16} This indicates that GaSe nucleated with random in-plane orientation. However, no polycrystalline rings were observed in the RHEED. The inverse of the ratio of spacing between m-plane and a-plane streaks in the RHEED image (Figure 1(b)) was measured to be 1.72, which is very close to the theoretical value of \sqrt{3}. XRD spectra of the samples grown in the range of conditions mentioned above, with the exception of the extremely Se-rich condition (T\textsubscript{sub} = 400°C, Ga:Se = 1:100) showed diffraction peaks corresponding to the (002) family of planes in layered-GaSe. However, with extremely Se-rich condition, the Ga\textsubscript{3}Se\textsubscript{3} phase was observed in XRD and a spotty RHEED pattern

![FIG. 1. RHEED patterns observed along [10 1 0] azimuth for (a) sapphire substrate and (b) GaSe film. (c) XRD spectra of GaSe grown at 400°C with Ga:Se of 1:200 (black) and 1:100 (red). Se flux was maintained at 1 × 10^{-6}Torr.](image-url)
was observed (Fig. S1 in the supplementary material). The growth window for GaSe in order to maintain a streaky RHEED pattern was found to be very narrow at a given substrate temperature. The RHEED pattern remained streaky and the intensity remained constant only at a certain Ga flux at a given substrate temperature. Higher Ga flux resulted in complete RHEED dimming and lower Ga flux resulted in a spotty RHEED pattern.

Surface morphology of GaSe films as a function of growth conditions is shown in Figure 2(a). At 350°C, a Ga:Se ratio of 1:50 resulted in a relatively smooth surface morphology, while a reduced Ga flux (Ga:Se = 1:100) was required at a growth temperature of 400°C. With an increase in substrate temperature from 350°C to 450°C, relatively smooth surface morphology could be maintained only with a reduction of Ga flux. This can be explained as follows. With an increase in substrate temperature, the sticking coefficient of Se is expected to reduce exponentially and hence the Ga flux that is required to maintain stoichiometry at the surface is lower at higher substrate temperatures (see supplementary material). This is also expected to result in a reduction in the growth rate of GaSe with an increase in the substrate temperature, assuming unity sticking coefficient for Ga adatoms at the growth temperature used. This observation is in agreement with the RHEED patterns observed during the growth. At the optimized conditions, where the adsorbed Ga and Se adatoms are close to stoichiometry, the RHEED pattern remained streaky throughout the growth. However, when the adatoms are close to stoichiometry, the RHEED pattern remained streaky while a reduced Ga flux (Ga:Se ratio to 1:100) was observed (Fig. S1 in the supplementary material). The RHEED pattern was found to be very narrow at a given substrate temperature. Higher Ga flux resulted in complete RHEED dimming and lower Ga flux resulted in a spotty RHEED pattern.

Control of in-plane orientation of the crystal domains during nucleation is very critical to obtaining single crystaline GaSe films. GaSe growth temperature was hence increased from 400°C to 575°C to control the in-plane orientation. Higher growth temperature necessitates higher Se flux due to reduction in sticking coefficient of Se with increase in the substrate temperature. This is qualitatively similar to the effect of flux ratios observed at lower growth temperature of 400°C. The Se beam flux was increased to \(1 \times 10^{-5}\) Torr.

Figure 4(a) shows the XRD spectra of GaSe films grown at different growth conditions on GaN substrates. The sample grown at 500°C with a Ga:Se ratio of 1:400 showed (111) oriented Ga_2Se_3 phase due to excess Se. With an increase in the Ga:Se ratio from 1:400 to 1:100 diffraction peaks corresponding to both GaSe(002) and Ga_2Se_3(111) planes were measured. With further increase in the Ga:Se ratio to 1:100, only GaSe(002) was detected at higher growth temperature of 575°C.

Figures 4(b)–4(e) show the RHEED patterns of GaN substrate and GaSe film grown at 575°C with Ga:Se = 1:100 along the [11 2 0] and [10 1 0] directions of the GaN substrate. The RHEED patterns corresponding to m- and \(\alpha\)-planes of GaSe (Figs. 4(d) and 4(e), respectively) were
observed along the same azimuth as GaN. The basal planes of GaSe was found to be perfectly aligned with the GaN substrate ([1120]GaSe//[1120]GaN and [1010]GaSe//[1010]GaN) and six-fold symmetry of GaSe was clearly observed. Unlike the film grown at 400°C with in-plane disorder, GaSe streaks corresponding to m- and a-planes of GaSe appeared only at every 60° azimuthal rotation spacing. The inverse of the RHEED spacing ratio between GaN and GaSe was found to be 1.170, which is very close to the ratio (1.173) of bulk lattice constants of GaSe (3.74 nm) and GaN (3.189 nm). This clearly suggests that the epilayer is fully relaxed and the growth proceeds by van der Waals epitaxy.

While the higher temperature growths led to single phase films, surface coverage was found to be incomplete. A step height corresponding to 1 ML of GaSe (0.8 nm) was measured at the edge of a triangular domain that grew on top of another triangular domain. Large area (10 μm × 10 μm) AFM scan (Fig. S2 in SI) and STEM measurements (Fig. S3 in SI) confirmed the observation of incomplete surface coverage from AFM scans. More details regarding the microstructure of the film is discussed later in the manuscript.

While high temperature growth of GaSe at 575°C resulted in (002)-oriented single crystal domains, the layers did not coalesce to form a continuous layer. Growth at 400°C with a Ga:Se ratio of 1:100 resulted in coalesced (002)-oriented GaSe layers with in-plane disorder. To obtain single crystalline GaSe with complete surface coverage, we designed a two-step growth method illustrated in Fig. 5(a).

After forming the nucleation layer at 575°C with 1 × 10⁻⁵ Torr of Se beam-equivalent pressure (BEP) flux, the growth temperature reduced to 400°C with a reduced Se flux of 1 × 10⁻⁶ Torr followed by 30 min of GaSe growth with 1:100 of Ga:Se ratio. Figure 5(b) shows the RHEED patterns along the [1120] and [1010] azimuth showing basal plane alignment. Six-fold symmetry was maintained after the second low temperature step, indicating that the basal planes are aligned with the GaN substrate and there is no in-plane disorder. Figure 5(c) displays XRD spectra of grown GaSe films after the first nucleation step (black) and the second low temperature growth step (red). The GaSe layers grew along the (002) orientation, and a higher order peak (006) was observed after second step growth mainly due to the increased thickness of the film. No additional phase such as...
Ga$_2$Se$_3$ was observed after the second step growth. An off-axis $\phi$ scan of the GaSe (103) plane was performed, and six peaks with 60° spacing were observed. The $\phi$ scan was repeated along the (102) plane of GaN and six peaks were found at the identical azimuth angles as GaSe, confirming the observation of basal plane alignment from RHEED.

Figure 6(a) shows the surface morphology of GaSe after the two-step growth process with a rms roughness of 1.1 nm. Surface coverage was found to be complete. Figure 6(b) shows the Raman spectra for GaSe grown after the first nucleation step (red), and the second low temperature step (blue). The Raman mode corresponding to a shift of 143 cm$^{-1}$ comes from the GaN/sapphire substrate. After the two-step growth, the Raman spectra matches the typical spectra expected from bulk GaSe with Raman modes at 134.3 cm$^{-1}$ ($A_{1g}$), 211.7 cm$^{-1}$ ($E_{1g}$), 250.2 cm$^{-1}$ ($E_{2g}$), and 307.6 cm$^{-1}$ ($A_{2g}$). The $A_{1g}$ and $A_{2g}$ modes correspond to the out-of-plane vibration modes, while the $E_{1g}$ and the $E_{2g}$ modes are associated with the in-plane vibrational modes of GaSe. In contrast to the enhanced intensity of these Raman peaks with the film thickness, no significant peak shift of $A_{1g}$ mode due to the change in thickness was observed because of sufficiently thick GaSe film after the first step growth. The appearance of $E_{1g}$ peak in GaSe has been reported in the literature. Nevertheless, at present the assignment of the new mode remains unclear. In addition, it is difficult to differentiate the polytypes from the Raman spectra as they show similar vibration modes.

Contour plot in Fig. 6(c) shows the intensity map of the dominant $A_{1g}$ peak over a 20 $\mu$m x 20 $\mu$m area indicating complete surface coverage. Thus, this two-step growth method enables formation of coalesced multilayer GaSe films.

The microstructure of MBE-grown GaSe films were investigated in detail using STEM measurements. STEM images from two regions of the GaSe nucleation layer grown
at 575 °C is shown in Figs. 7(a) and 7(c). An abrupt GaSe/GaN interface and 5–8 GaSe monolayers separated by van der Waals gaps could be clearly resolved in the STEM images. Ball-and-stick model generated using VESTA is superimposed on the atomic resolution image to identify the stacking sequence. The stacking sequence indicates that the films grown are of the ε-GaSe polytype, in Fig. 7(b). However, a 60° rotation of the Se-Ga-Ga-Se tetralayer is observed in the region highlighted in Fig. 7(d), in which the Ga atoms sit on top of Se atom. Figure 7(f) shows the simulated crystal structure of ε-GaSe with a 60° rotation of every other layer resulting in β-GaSe polytype crystal structure. Such a rotation of the basal plane would not be captured in the RHEED or XRD measurements due to the six-fold symmetry of both the β and ε polytypes of GaSe. In spite of the rotation of the first tetralayer, subsequent GaSe stacking is pure ε-type. This may be attributed to the fact that the ε polytype is energetically more stable than the β type. Similar lattice rotations and the resultant formation of grain boundaries have been reported in the case of MoS2.4–6 Dumcenco et al.46 has reported simulated data on the binding energies for MoS2 and sapphire substrate as a function of orientation angle of MoS2 grains. It was pointed out that only 0° or 60° orientations of the lattice were energetically favorable and stable.

The microstructure of the coalesced GaSe films grown using the two-step method was also investigated using cross-section STEM. Total number of layers after two-step growth was found to be 25–27 from STEM measurements, and 20–22 layers were grown in the second step. This implies a growth rate of 0.7 nm/min, which is similar to the low growth temperature (Tsub = 400 °C) sample. The first five layers are identical to the nucleation sample. A region with 60° rotation of first layer was also observed in the two-step sample and is shown in Fig. 8(a). However, inclusions of β-type is observed along with the dominant ε-type GaSe. Figure 8(b) shows a magnified image of a region cropped from the boxed region in Fig. 8(a). Surface reconstruction of the GaN surface can be clearly observed in the image. Ga atoms (red arrow) at the surface are bonded directly to a Ga atom below it, suggesting a 1 × 1 reconstruction of Ga atoms. On top of the surface Ga atoms, two atoms (green

(f) Ball-and-stick model of ε- and β-GaSe types. 60° rotation of every other layer in GaSe structure in ε-type turns out to be β-type.

![FIG. 8.](image-url) (a) and (b) Cross sectional STEM images of GaSe after two-step growth taken from different region. (c) Magnified image from boxed area in (b). Ball-and-stick models of GaSe and GaN are also presented. (c) Defects formed in the middle of GaSe film are marked with an arrow.
arrows) were observed above every second Ga atom. We hypothesize that these could be Se atoms passivating the GaN surface. This suggests that van der Waals epitaxy can be used to maintain surface reconstructions on the GaN surface, and which could have important implications for Fermi level pinning and dangling bond termination at heterostructure interfaces. The electronic properties of these artificial two-dimensional interfacial layers could be of great interest, but are outside the scope of the present work. We also observed that defects formed in one area of GaSe film did not propagate along c-axis towards surface due to the absence of bonding between individual 2D layers (Fig. 8(c)). However, certain amount of defect propagation is indeed observed and further careful study is required to understand extended defects in 2D crystals. The GaSe growth study has provided an overall understanding of 2D material growth. The growth rate is predominantly determined by the amount of Ga flux. However, unlike Ga, migration-enhanced epitaxy may be more effective in the case of TMD growth using refractory metal, such as Mo, W, or Nb.

IV. CONCLUSION

In summary, we have developed a two-step method to grow continuous, crystalline films of multilayer e-GaSe on GaN(0001). To achieve this, we first optimized the growth of GaSe films on c-plane sapphire and GaN(0001) substrates in the low temperature regime (optimized $T_{\text{sub}} = 400^\circ \text{C}$). On both substrates, this produced continuous films of (002)-oriented GaSe with random in-plane orientation of domains. In contrast, high temperature (575\(^\circ\)C) growth on GaN(0001) resulted in discontinuous GaSe films, but with well-defined in-plane orientation aligned to the substrate lattice. For continuous, crystalline films, we combined these two growth modes into a two-step process where the first step is a high temperature growth to establish well-defined in-plane orientation, and the second step is a low temperature growth to coalesce the nucleated domains into a continuous film. This work illustrates the advantage of molecular beam epitaxy in realizing the growth of large area 2D crystals with high material quality.
